REVIEW

Effects of lifestyle factors on fertility: practical recommendations for modification

Mathias Abiodun Emokpae and Somieye Imaobong Brown

Abstract

The role that lifestyle factors play in fertility issues has generated some amount of interest and questions among stakeholders. This review aims to highlight the impact of lifestyle behaviors on the fertility potential of an individual and what can be done to prevent or improve reproductive outcomes. Relevant published articles on the effect of lifestyle behaviors were obtained from Medline, Pubmed and Google scholar search engines for the study. The review of the literature indicates a negative impact of modifiable lifestyle factors such as fat-rich diets, delayed childbearing/age of starting family, smoking, alcohol misuse, sexual behavior, anxiety/depression and perception/beliefs were associated with fertility. The ensuing stress precipitates social behaviors such as excessive alcohol and caffeine consumption, tobacco smoking, misuse of recreational drugs/medications, which increases the risk of sexually transmitted diseases and infection leading to infertility. Practical recommendations to modify lifestyle behaviors and the impact of misconception of Assisted Reproductive Technology in the treatment of infertility are discussed. The need to make appropriate behavioral changes to stem the tide of infertility in Nigeria is imperative. More reproductive health education is needed to create the necessary awareness of the etiologies of infertility and the importance of *in vitro* fertilization treatment as a means of conceiving 'natural' babies is suggested.

Lay summary

Scientific evidence has suggested that modifiable lifestyle factors (consumption fat-rich diets, delayed childbearing/age of starting family, smoking, alcohol misuse, sexual behavior, anxiety/depression and perception/beliefs) play important roles in the general health and wellbeing of individuals including fertility. Evidence exists of an association between lifestyle behaviors and infertility in both men and women. Understanding the various processes through which modifiable lifestyle behaviors impair fertility will help to assist in the management of affected individuals. We conducted a comprehensive review of published studies to assess how lifestyle factors inhibit fertility and practical ways to ameliorate them. This review also deals with the misconception of Assisted Reproductive Technology in the treatment of infertility. The need to make appropriate behavioral changes to stem the tide of infertility in Nigeria is imperative. More reproductive health education is needed to create the necessary awareness of the causes of infertility and the importance of *in vitro* fertilization in the treatment of infertility.

Key Words: ► lifestyle behaviors ► infertility ► humans

Reproduction and Fertility (2021) 1 R13–R26

Introduction

Reproduction is an important biologic event in all living organisms. Anything that threatens reproductive health will trigger a significant response from the scientific community, since the continuous existence of any species is dependent upon the sound reproductive health of the parent species. There are reports of deteriorating reproductive health indices since the last 5–6 decades ago from different parts of the world especially in industrialized/developed countries as a result of modifiable lifestyle factors (Kumar *et al.* 2018).

Lifestyle factors refer to the modifiable behavior and ways of life that could influence the general health and wellbeing of individuals including fertility (Acharya & Gowda 2017). The role of lifestyle factors in the etiology of infertility has generated a growing interest among researchers. Several authors have provided evidence of an association between lifestyle behaviors and infertility in both men and women, they include; delayed childbearing due to pursuit of career or education, age of starting a family, smoking, eating of fat-rich diets, alcohol and caffeine consumption, exercise, risky sexual behaviors, drug misuse, anxiety/depression, cellular phones and radiation among others (Araoye 2003, Adewumi 2017, Fehintola *et al.* 2017, Durairajanayagam 2018, Emokpae & Chima 2018,

Ilacqua *et al.* 2018, Ikyernum *et al.* 2019, Silvestris *et al.* 2019, Alabi 2020) (Fig. 1).

According to the World Health Organization, about 20–30% of couples worldwide are infertile, and up to 80 million women are affected by the condition with about 50% of all women in developing countries are infertile (Ombelet *et al.* 2008). The prevalence of infertility in sub-Saharan African ranges between 20 and 40% and the problem is shared equally by both men and women (Emokpae & Uadia 2015). It has been estimated that about one in six couples or approximately 15% of the population in industrially developed countries is affected (Sharma *et al.* 2013). Infertile couples suffer both emotional and psychological trauma due to pressure from family members and society. Fortunately, most of the causes of infertility are treatable with major procedures belonging to the assisted reproductive technology (ART) methods. However, the normalization of some modifiable lifestyle factors could restore normal oocyte maturation in women and improve semen quality in the males (Ilacqua *et al.* 2018). The understanding of the various mechanisms whereby modifiable lifestyle behaviors impair infertility in both males and females will go a long way to assist in the management of affected subjects. This review seeks to highlight the adverse effects of some lifestyle behaviors and suggests ways to optimize the infertile couple's chances of obtaining conception and live a better quality of life.

Figure 1 Schematic representation of lifestyle behaviors on infertility in both males and females.

Materials and methods

Over 1000 articles were initially identified from the Medline, Pubmed and Google scholar search engines and after review of the titles and abstracts, about 150 articles that met the inclusion criteria of major lifestyle factors associated with both male and female infertility were systematically reviewed. This narrative review is largely focused on Nigeria and the recommendations could be country-specific. The need to change the erroneous belief and perception of some Nigerians that children conceived through the assisted reproductive technique are ‘artificial’ is emphasized.

Major lifestyle behaviors that may affect fertility

Lifestyles factors are obviously under the control of the individual and are modifiable to improve the wellbeing of humans. Lifestyle factors could affect reproductive health either positively or negatively (Ilacqua *et al.* 2018). Infertility can be defined as the absence of conception within one year of unprotected sexual intercourse, while fertility is the capability of producing an offspring (Aydin *et al.* 2014). The new trend of modern lifestyle is that people delay starting a family due to educational and career pursuit, such individuals are older and overweight. Aging is associated with degenerative changes at the levels of all organs and systems, and as such fertility may be affected (Balasch & Gratacós 2011). Consequently, such individuals engage in excessive alcohol consumption, tobacco intoxicated, and abuse illicit substances (Harris *et al.* 2011). These lifestyle behaviors expose one to the risk of infertility, but because of the financial stability that comes with having a career; most believed they can afford assisted reproduction. The causes of infertility are varied ranging from endometriosis, ovulatory disorders, poor sperm quality, and unexplained conditions among others. Some authors suggested that adverse lifestyle factors such as smoking, alcohol consumption, and caffeine can have an additive effect on fertility (Ilacqua *et al.* 2018). A study that examined couples who were trying to conceive naturally over 12 months, reported that only 38% of couples with 4 adverse lifestyle factors conceived compared to 52% with 3, 62% with 2, and 71% with one. Where no adverse lifestyle factors were present, 83% of couples became pregnant (Burton 2014).

Delayed childbearing/age of starting a family

Human reproduction is greatly influenced by age. This is because so many physiological changes take place both in

men and women as they grow older (Emokpae & Uadia 2017, Emokpae & Igharo 2020). This is compounded by the powerful effect of socioeconomic and environmental factors which have not helped to improve reproductive potential despite improved technology and advancement in science.

Delay in starting a family/aging among men may lead to the production of poor quality spermatozoa. Semen parameters begin a steady decline as early as age 35 (Stone *et al.* 2013). Semen volume and motility decrease and morphology may become increasingly abnormal. Although age affects both males and females, the most significant impact on reproduction is maternal age. A woman is born with all egg cells she will ever have. They reduce in number and quality over the years and by the time she gets to 35 years, her fertility is declined (Baird *et al.* 2005). Incidence of genetic abnormality and spontaneous abortion also increases with maternal age (Kroon *et al.* 2011). A benchmark of natural fertility is usually provided by the Hutterite population which lives a relatively simple communal lifestyle that excludes the use of contraception. They showed a progressive decline in the rate of pregnancies with an increase in female age (Tyden *et al.* 2006). The data of Wood demonstrates that delay in starting a family and aging could lead to a 50% decrease in apparent fertility potential at age 35 years. Fecundability is the ability to achieve a pregnancy within a menstrual cycle. This effect is also similar in women undergoing ART with decreased pregnancy rates with age (Liu *et al.* 2017). The biological clock regulating the female reproductive life span has existed to reduce the complications associated with abnormal pregnancy outcomes in advancing age and to save energy for somatic maintenance (Luo & Murphy 2011, Emokpae & Igharo 2020). Despite this substantial evidence of a decline in fertility with age, men and women are often unaware of the risk associated with delayed childbearing due to the increasing social behavior where education and career pursuits coupled with economic factors keep both gender out of relationships and childbearing until the late thirties and early forties (Luo & Murphy 2011). Couples need to understand the biology of aging concerning fertility in both sexes to enable them and healthcare givers to make an informed decision regarding delayed childbearing, age of starting a family, and counseling of those seeking fertility treatments (Emokpae & Igharo 2020). Although men could produce semen even at an older age, increased paternal age has been reported to be a major determinant for testicular function, sex hormones, sperm quality, sperm DNA integrity, telomere length, and

epigenetic factors (Arslan *et al.* 2017, Ilacqua *et al.* 2018). These changes due to aging adversely impact fertility and reproductive outcomes such as congenital birth defects, fetal death, recurrent abortion, and infertility. Paternal age has also been linked with autism, schizophrenia and bipolar disorders, and achondroplasia (Arslan *et al.* 2017). Higher oxidative stress occurs in aged couples as a result of an imbalance between reactive oxygen species generation and available antioxidants in the circulation. This was aptly demonstrated in an experimental study that showed that aging leads to a decline in fertility and the numbers of Sertoli and germ cells in mice with the complete absence of catalase (CAT-null(cat−/−) or/and superoxide dismutase 1 (SOD-null(sod−/−) (Tyden *et al.* 2006). This is an indication that these antioxidant enzymes are vital in the maintenance of germ cell quality in advanced age. Paternal age is reported to adversely affect testicular volume, alters the structure of seminiferous tubules (Janevic *et al.* 2014), and reduces blood supply to the testes (Wasiu *et al.* 2012). Sex hormone secretion is affected by aging; there is a decline in the secretion of testicular inhibin B by Sertoli cells coupled with increased secretion of follicle-stimulating hormone (FSH) (Ilacqua *et al.* 2018). Since there are reductions in the numbers of Leydig cells, the biosynthesis of testosterone is affected. Aging was also reported to alter the hypothalamic–pituitary–gonadal axis function, hence leading to changes in the other reproductive hormones. The exacerbated effect of aging on increase DNA fragmentation was reported to be a contributing factor to the low success rate of assisted reproduction technology (ART) treatment in infertile couples (Alvarez Sedó *et al.* 2017). Individuals should be counseled to start a family at the peak of reproduction period as delay can adversely affect fertility potentials. Also, caution may be applied when using spermatozoa of aged-men during treatment with ART to avoid the risk of possible transmission of genetic disorders to offsprings.

Nutritional factors

Nutritional problems are strikingly different in developing nations where deprivation, undernutrition, and malnutrition are the major problems while eating disorders and obesity are very common in developed countries. Obesity is, however, increasingly common in developing countries due to globalization. The reproductive system is extremely sensitive to influences from the external environment. This is because it involves energy expenditures and it is only sensible that the physiological control mechanisms of the reproductive

axis be closely linked to the nutritional status as it is in living organisms (Giahi *et al.* 2016). Several factors such as genetic, environmental and behavior contribute to the increasing trend in overweight and obesity. In some cases, the preponderant of cheap high-calorie but nutrient-poor foods in the last four decades has contributed to the high prevalence of obesity all over the world (Giahi *et al.* 2016).

In females, reproduction involves much greater energy expenditures than for males and as a protective mechanism against under-nutrition, ovarian activity is suppressed in women with eating disorders and exercise-induced amenorrhea through pathways in the hindbrain. The combined prevalence of *Bulimia nervosa* and *Anorexia nervosa* is approximately 5% among women of reproductive age. *Bulimia nervosa* is an eating disorder that is characterized by binge eating which is followed by fasting or self-induced vomiting or purging. It is an emotional disorder that makes one have a distorted body image and an obsessive desire to lose weight. *Anorexia* on the other hand is also an eating disorder that is more of a psychological condition marked by extreme self-starvation due to a distorted body image. The likelihood of cure is higher with *Bulimia nervosa*. Both disorders suppress ovulation in severely affected women and account for up to 60% of women with anovulatory infertility (Tabler *et al.* 2018).

Some nutritional factors may affect male fertility and evidence suggesting a direct association between nutritional altitude and poor semen quality has emerged. High-fat diets inhibit reproduction by affecting the physical and molecular structure of not only sperm cells but also the developing fetus and offsprings (Rato *et al.* 2014). Some experimental studies have shown that feeding mice with high-fat diets resulted in long-term alterations in the reproductive system, and the metabolic programming mechanisms; such as a decrease in both height and diameter of the seminiferous epithelium, and seminiferous tubules, respectively (Ibáñez *et al.* 2017). This also resulted in decreased sperm concentration, viability, and DNA integrity. It has long been recognized that normal testicular function is responsive to changes in whole-body metabolism, and that testicular metabolism can be affected by the intake of high-energy diet (Rato *et al.* 2013) and in people with obesity. Studies have suggested that reproductive health can be enhanced by modification of dietary intakes such as fruits and vegetables, legumes, and fish. The regular intake of foods rich in fruits, vegetables, legumes, and fish was associated with better sperm quality (Karayiannis *et al.* 2017) and a lower DNA fragmentation index than subjects who do not

take such foods regularly. Regular intake of red meat was inversely associated with sperm quality. [Table 1](#) shows the schematic representation of various lifestyle behaviors on infertility.

In a study of health and lifestyle among Finnish men and women with infertility, it was reported that infertile women under 50 years consumed more unsaturated fat, less saturated fat, and consumed more alcohol than their fertile counterparts ([Revonta et al. 2010](#)). The effectiveness of lifestyle intervention was assessed among some infertile women with obesity, and the authors reported that lifestyle intervention increased the natural conception rate among anovulatory infertile women with obesity, but did not affect the rate of healthy live birth ([van Oers et al. 2016](#)). Infertile women are therefore counseled to maintain a healthy eating habit to avoid the accumulation of body fats with may impair ovulation ([van Oers et al. 2016](#)). The evaluation of lifestyle habits and the modification of unhealthy habits by trained health providers with specific management, like systematic folic acid supplementation in females attempting to conceive may yield the desired outcomes ([Silvestris et al. 2019](#)). High insulin levels and insulin resistance are associated with body fat accumulation, polycystic ovarian syndrome, metabolic syndrome, and all have serious implications for female infertility. Hyperinsulinemia enhances the

excess biosynthesis of androgen and lipids from the theca cells. Increase production of estrogen by the fat cells and primary sex organs that occur in a state of high body fat is interpreted as birth control by the body, hence limiting the chances of conception ([Wasiu et al. 2012](#)).

Smoking

Cigarette smoking has been associated with adverse effects on fertility although not widely recognized. It also increases the risk of congenital cardiac disease. In males, smoking has been observed to reduce sperm concentration, morphology, and motility as well as increased DNA damage ([Caserta et al. 2013](#)). The exact mechanisms underlying the impact of smoking on sperm quality is not completely understood. Tobacco smoke contains several substances such as nicotine, cadmium, lead, superoxide, and hydroxyl radicals that can adversely affect reproductive health. Superoxide and hydroxyl radicals can take part in the Fenton reactions to produce hydrogen peroxide and ultimately caused oxidative stress and cause DNA damage ([Taha et al. 2012](#)). Cadmium and lead have been reported to cause DNA strand breaks while nicotine, superoxide, and hydroxyl radicals can induce dsDNA breaks in sperm DNA ([Ilacqua et al. 2018](#)). A study that evaluated the levels of DNA fragmentation index (DFI)

Table 1 Summary of study findings of lifestyle behaviors on infertility in Nigeria.

Reference	Study design	Population size	Type of lifestyle behaviors	Reproductive health effect
Alabi (2020)	Qualitative	15	Social, traditional and religious beliefs	Low acceptance of surrogacy practice
Emokpae et al. (2020)	Cross-sectional	400	Nutrition	Poor semen quality
Akande et al. (2019)	Cross-sectional	202	Perception and beliefs	Poor acceptance surrogacy and negative attitude toward IVF treatment
Ikyernum et al. (2019)	Cross-sectional	600	Risky sexually behavior	Poor semen quality
Emokpae et al. (2019)	Experimental	24 adult rabbits	Drug abuse (tramadol)	Increased lipid peroxidation
Osabuohien & Emokpae (2018)	Experimental	30 adult rabbits	Alcohol abuse	Low sex hormone levels
Emokpae & Chima (2018)	Cross-sectional	122	Paternal aging	High oxidative stress and apoptosis
Adewumi (2017)	Review	Several articles	Cultural beliefs/cost	High emotional/financial stress
Okafor et al. (2017)	Cross-sectional survey	589	Perception and traditional belief	Unscientific perception, misconception of IVF treatment
Emokpae & Egho (2017)	Experimental study	30 adult rabbits	Alcohol abuse	Increased oxidative stress
Osian et al. (2019)	Survey	348	Perception	Low knowledge of IVF
Oremosu & Akang (2015)	Experimental	36 adult Sprague–Dawley rats	Alcohol abuse	Low sex hormone levels, poor semen quality and high oxidative stress.
Omoaregba et al. (2011)	Cross-sectional	100	Anxiety and depression	High psychological distress
Makanjuola et al. (2010)	Case–control	320	Anxiety and depression	High rate of psychiatric morbidity, lack of support from husbands' and husband's relatives.

in infertile smokers and infertile non-smokers reported a significantly higher ($P < 0.001$) DFI (37.66%) among infertile smokers than infertile non-smokers (19.34%) and controls (14.51%) (Wright *et al.* 2014). The study demonstrated the contribution of smoking to infertility. The effect of smoking on sperm quality was reported to be more pronounced in heavy smokers (those who smoke >20 cigarette sticks/day) and moderate smokers (10–20 cigarette sticks/day) than mild smokers (1–10 cigarette sticks/day) (Sharma *et al.* 2016).

In females, smoking can lead to the increased thickness of the *zona pellucida* in smokers which makes sperm penetration difficult (Ilacqua *et al.* 2018). Menopause has been reported to occur 1–4 years earlier in smoking women when compared to non-smoking women (Vanegas *et al.* 2017). Cigarette contains several harmful constituents that have been detected in the follicular microenvironment of smokers such as cotinine and cadmium thereby altering hormone levels in the luteal phase and could affect the developing follicle. Smoking in women significantly decreases the chance of conception by disrupting ovarian function and depleting its reserve.

Oxidative stress is one of the main causes of DNA fragmentation in male infertility but maybe modifiable in several ways. Sources of oxidative stress as outlined in this paper should be evaluated in infertile men as part of a treatment protocol. The use of antioxidants supplementation has been reported to have some benefits, but these antioxidant levels have to be determined whether there are deficiencies or not so that over-supplementation is avoided. It is important to maintain a delicate balance between oxidants/antioxidants to ensure fertility, successful fertilization, and pregnancy. Quitting smoking may improve fertility in those who smoke previously. A follow-up study of men who quitted smoking revealed that every additional year following cessation of smoking reduced the risk of ART failure by 4%, especially between clinical pregnancy and live birth (Vanegas *et al.* 2017). Therefore, cessation of smoking and avoiding exposure to tobacco smoke among couples may improve the chances of conception.

Alcohol consumption

Alcohol is the most commonly abused substance known and used for celebration and relaxation since ancient times. Apart from damaging other organs of the body such as the liver, heart, and nervous system, it also affects reproductive health. The kind of damage done depends on

the type, amount, and duration of alcohol consumption. Alcohol depletes many essential nutrients from the body such as vitamin B, zinc, iron, magnesium, calcium, sodium, potassium, etc., and these vitamins and minerals are needed for most functions including reproduction. There is excess estrogen and decrease testosterone in all types of alcohol misuse (Ilacqua *et al.* 2018). Alcohol is a known teratogen and its consumption has been reported to decrease fertility (Oremosu & Akang 2015). An animal study that evaluated the effect of chronic alcohol consumption on reproductive hormones and semen characteristics, it was reported that serum testosterone, follicle-stimulating hormones (FSH), luteinizing hormone (LH), sperm count, and motility correlated inversely with increasing concentrations of alcohol consumed. Also, the concentration-dependent testicular morphological changes were observed (Osabuohien & Emokpae 2018). It was observed that chronic consumption of alcohol did not only lower the levels of sex hormones and sperm quality but also led to weight loss in the animals as a result of changes in dietary habits (Osabuohien & Emokpae 2018). Chronic alcohol consumption also alters macronutrients and micronutrients absorption in the small intestine. Studies have shown that the absorption of amino acids, lipids, and glucose is impaired during chronic over-consumption of alcohol. An earlier report indicated that chronic consumption of alcohol above 12% v/v concentration has the potential to increase serum markers of iron status and oxidative stress in experimental animals (Emokpae & Egho 2017). The authors suggested that chronic ingestion of high concentrations of alcohol may have adverse effects on sex hormones, testes, epididymis, and ultimately fertility potential (Oremosu & Akang 2015, Osabuohien & Emokpae 2018). Therefore careful use of high concentrations of alcohol or better still abstinence is advised since alcohol suppresses the synthesis of hormones at the levels of the hypothalamus, the anterior pituitary, and the gonads (Oremosu & Akang 2015, Osabuohien & Emokpae 2018). Damage to the nervous system in men can results in sexual impotence due to loss of libido and erection (Durairajanayagam 2018).

Alcohol is commonly consumed by women of reproductive age and is associated with several reproductive health risks. There is no data on the prevalence of alcohol use and misuse in Nigeria but 86.4% of people aged 18 years and above are reported to have consumed alcohol at a point in their lives while 56% are current users in the United State of America (Abuse 2015). Studies in both human and animal models have observed that chronic

alcohol consumption resulted in changes in ovulation and menstrual cycle regularity (Oremosu & Akang 2015). Although acute alcohol consumption may not harm the menstrual cycle, it has been reported to negatively affect fertility treatment outcomes. Chronic over-consumption of alcohol may lead to a decline in ovarian reserve and fertility potentials in women. Markers of ovarian reserve and fertility potentials (FSH, anti-mullerian hormone (AMH) and antral follicle count) were reported to be lower among alcohol users than non-users (Abuse 2015). This was supported by evidence indicating that women who drink alcohol experience menopause at an earlier age than non-drinkers. On the contrary, there is no evidence linking mild or moderate alcohol consumption with female infertility. Some authors have reported no association between alcohol consumption and ovulation and fecundability (Mikkelsen *et al.* 2016). Even though the findings are inconsistent, individuals who are currently being treated for infertility maybe enjoined to abstain or reduce alcohol consumption.

A woman may suffer from infertility due to the derangement of the hormonal system by alcohol even with mild consumption. If she is pregnant there may be a risk of abortion and could also cause a low birth weight of the child with various congenital abnormalities if the pregnancy progresses.

Those who misuse alcohol early in life are more likely to indulge in risky sexual behavior which can expose them to sexually transmitted diseases such as Chlamydia trachomatis and HIV/AIDS. Sexually transmitted infections have been associated with infertility in several studies (Okonofua *et al.* 2005, Umeora *et al.* 2007). Genital tract infection is an important etiological factor for sub-fertility and infertility in Nigeria. It can lead to poor semen quality (Owolabi *et al.* 2013), obstruction of seminal tract (Okonofua *et al.* 2005) and tubal blockage (Umeora *et al.* 2007, Wasiu *et al.* 2012). Chronic dehydration is usually associated with heavy drinkers but appropriate hydration is important for a healthy reproductive function. Without enough water, men may experience poor quality erections, low seminal volume, and prostate infections. Women can develop persistent vaginal dryness and suffer greater susceptibility to a yeast infection.

Alcohol consumption and the effectiveness of IVF treatment

There is evidence that suggests that alcohol consumption negatively impacts ART treatment outcomes. A prospective study of 221 subjects undergoing IVF or gamete

intra-fallopian transfer (GIFT) reported a 13% decrease in the numbers of oocytes retrieved, a 2.86 times likelihood of not achieving pregnancy, and 2.21 times of higher risk of abortion among women who consume alcohol than controls (Klonoff-Cohen *et al.* 2003). These findings suggest fertilization failure, as alcohol intake can reduce the success rate of IVF treatment by decreasing oocyte yield and live birth rates. Therefore, women seeking IVF treatment are encouraged to abstain or minimize alcohol consumption before commencing treatment.

Caffeine

Caffeine is a stimulant that has enabled it to be used as a beverage (tea, soft drink, chocolate, etc.). It affects the nervous system and various other organs including the reproductive system. It has over 1000 active compounds (stimulants), and a high intake of caffeine more than 5 cups or 500 mg per day delays pregnancy. It interrupts egg fertilization and implantation process (Olsen 2018). Several observational studies and meta-analyses have reported that maternal caffeine consumption may be associated with major adverse pregnancy outcomes. Some authors reported significant dose-dependent associations that are suggestive of causation while others observed no threshold of consumption below which associations were absent. Consequently, available data does not support health advice that assumes 'moderate' caffeine consumption during pregnancy is safe. However, current evidence supports pregnant women and would-be mothers to avoid caffeine consumption (James 2020). Conversely, the American College of Obstetrics and Gynecologist (2010) implied that moderate caffeine did not harm the fetus of pregnant women but its high intake (more than 540 mg every day) resulted in low fetal weight and length. It also causes withdrawal symptoms such as headaches, nausea, irritability, etc. It may also increase the risk of miscarriage because it can cross the placenta barrier. A high level of caffeine consumption has been associated with an increased risk of stillbirth (Minguez-Alarcon *et al.* 2018). There is no definite amount or safe level of caffeine consumption but about 200 mg is considered moderate for those breastfeeding, pregnant, or trying to conceive women.

The regular consumption and abuse of high caffeine energy drinks are increasingly popular. These caffeine-rich energy drinks have been reported to readily pass through biological membranes and rapidly distributed all over the body and may impair male gonadal development and function (Minguez-Alarcon *et al.* 2018). The mechanism by

which caffeine impairs infertility is not well understood, and there are conflicting reports on its harmful effects by some authors (Ilacqua *et al.* 2018).

Physical exercise

Regular exercise affects all individuals' general health and wellbeing and probably provides some protection from obesity, cardiovascular disease, type 2-diabetes, psychological stress, etc. Exercise increases insulin sensitivity and improves ovarian functioning and may improve the chances of achieving conception. There is evidence to suggest an association between physical exercise and infertility, as exercise may contribute to a reduction in energy balance, leading to amenorrhea and irregular ovulation (Silvestris *et al.* 2019). Physical exercise is beneficial to overweight or obese infertile women. The findings from an interventional study indicated that physical exercise combined with weight loss was associated with improved fertility among obese women. On the contrary, a cohort study of over 5000 women with a healthy BMI range ($<25 \text{ kg/m}^2$) showed that rigorous exercise was inversely associated with fertility potentials, but was positively associated with fecundability among overweight and women living with obesity (Wise *et al.* 2012). Sedentary lifestyle behavior refers to time spent doing little or no movement while awake or sitting. It is one important modifiable risk factor for infertility since biological evidence supports the association of physical activity and infertility. Women who engage in rigorous physical exercise may be at risk of infertility due to anovulation and implantation defect.

Most researches about physical fitness and reproduction are primarily focused on athletes rather than those with moderate level fitness. After BMI adjustment, each hour of vigorous exercise per week was reported to be associated with a 5% reduction in risk to protect ovarian functioning. However, in obese infertile women, increased physical fitness, and psychological wellbeing resulted in significant improvement in ovulation and conception (Silvestris *et al.* 2019). Female athletes who engage in excessive exercise and have poor dietary habits are at risk of developing a low BMI which may result in a low estrogen level. This affects the menstrual cycle and ovulation.

The quality of sperm parameters of men performing the exercise for one hour, at least three times a week were 15.2% better than that those who perform exercise less frequently or excessively (9.7%). The parameters investigated by the authors were the morphology, count,

concentration, and motility (Aydin *et al.* 2014). There are however conflicting data on the effect of physical exercise on male fertility potential. Earlier studies have indicated that regular vigorous exercise can adversely affect semen quality and testicular function, a situation attributed to testicular heating, oxidative stress, DNA fragmentation, and gonadotropin inhibition (Silvestris *et al.* 2019). Conversely, some authors have observed that individuals who engage in regular exercises had better semen quality than sedentary control subjects (Lalinde-Acevedo *et al.* 2017). Others have reported that moderate regular training may reduce seminal plasma oxidative stress than rigorous regular exercise (Silvestris *et al.* 2019). Regular moderate exercise is recommended and may improve fertility potential among infertile subjects since rigorous physical activities might expose individuals to an increased risk of poor reproductive function.

Sexual behavior

Sexual promiscuity greatly increases the risk of sexually transmitted diseases, such as gonorrhea, chlamydia trachomatis, herpes, syphilis, and HIV. Many of the sexually active individuals are less likely to use contraceptives which may lead to sexually transmitted infections (STIs), and unintended pregnancies. The increased risk of unplanned pregnancy and criminal abortions further aggravates the risk of STIs and infertility. Sexually transmitted infections (STIs) are common problems often associated with infertility in Nigeria (Emokpae & Uadia 2015). Studies have associated STIs with risk for male infertility in southern Nigeria (Okonofua *et al.* 2005), and men who reported having chronic penile discharge, painful micturition, genital ulcers, and testicular pain were more likely to be infertile. Another study reported 173/500 (34.6%) of STIs prevalence among males investigated for infertility in Kano, Northern Nigeria (Emokpae *et al.* 2009). Early diagnosis and treatment of STIs is key to the prevention of sexually transmitted infections-induced infertility.

Drug abuse

Women are more vulnerable to long-term drug abuse compared to men due to the difference in physiology, weight, hormone levels, etc., that can affect the breakdown of these drugs in the body (Center for Behavioral Health Statistics and Quality 2017). Heroin and methadone are known to cause amenorrhea. Intravenous drug use exposes one to HIV and AIDS and also when someone is under

the influence of such drugs that individual can partake in risky sexual acts that make him or her susceptible to sexually transmitted infections (STI), including Human Papilloma Virus (HPV). This is linked to increased cervical cancer risk among women. Drugs such as marijuana, heroin, methamphetamine, cocaine could easily pass through the placenta to the fetus thereby increasing the risk of low birth weight, birth defects, premature birth, sudden infant death syndrome (SIDS), and changes in physical features of the fetus. Women who use illicit drugs during pregnancy are up to two times more likely to have a stillbirth, as prescription drugs such as non-steroidal anti-inflammatory drugs NSAID show a correlation with female infertility (Forray 2016).

In males, this risky behavior produces similar outcomes of STIs and infertility which usually presents with problems of sexual dysfunction. The use of methamphetamine and cocaine can lead to erectile dysfunction and delayed orgasm in men who initially may have experienced benefits such as heightened arousal. Chronic use of marijuana decreases testosterone secretion from Leydig cells, spermatogenesis, sperm motility, etc. (Forray 2016). Marijuana contains 'hashish' which also is capable of binding to receptors in a reproductive organ such as the uterus and ductus deference (Aydin *et al.* 2014).

Cellular phones and radiation

Emerging evidence suggests the detrimental effect of cellular phones on fertility. The numbers of mobile phone users are increasing by the day and several users keep and/or store mobile phones in their trouser pockets. The mobile phone has been suggested as a source of damaging radiation to the male reproductive organs. Increased levels of DNA fragmentation index have been reported in mobile phone users (Wright *et al.* 2014). These gadgets transmit or receive radiofrequency electromagnetic waves that have adverse effects on sperm motility, number, and morphology. Higher serum free testosterone and a lower luteinizing hormone (LH) level were reported among some users of cellular phones than control subjects who do not use cellular phones (Ilacqua *et al.* 2018).

Anxiety and depression

Some authors have observed that anxiety, depression, and violence could adversely impact fertility (Makanjuola *et al.* 2010). Studies in Nigeria have revealed how the varying forms of these habits affect fertility among

infertile women. Procreation is considered as a means to enhance or solidify a woman's status in the family and community in Nigeria (Makanjuola *et al.* 2010). When this is not achieved as desired, marital harmony is threatened, anxiety and depression may occur. In a study of predictive factors for psychiatric morbidity among infertile women, it was observed that 48.8% out of 160 respondents presented with psychiatric morbidity. Also, the absence of support from their husbands and husband relatives, unfair treatment, discrimination, and induced abortion were significantly higher ($P < 0.001$) among infertile women than control subjects. The psychosocial challenges were not different between primary and secondary infertile women. The authors emphasized early identification of psychiatric morbidity and more public enlightenment to enhance moral and psychosocial support for women with infertility in Nigeria (Makanjuola *et al.* 2010). Surprisingly, the reported rate of psychiatric morbidity (48.8%) was higher than previously reported from the same center. Some authors have reported a rate of 47.3% of psychiatric morbidity among infertile women from Akwa Ibom State in Nigeria. This is an indication that the challenge is widespread in Nigeria. Lack of support from their husbands, unfair treatment, and discrimination from their husbands and their relatives toward infertile women were associated with anxiety, depression and other psychosocial problems (Abasiubong *et al.* 2008, Bhonage *et al.* 2014).

There is enough scientific evidence to suggest that anxiety and depression could severely affect spermatogenesis, mainly by depressing testosterone secretion. The hypothalamic-pituitary-adrenal (HPA) axis has a direct inhibitory action on the hypothalamic-pituitary-gonadal (HPG) axis and Leydig cells in the testes. The gonadotropin inhibitory hormone (GnIH) also has an inhibitory effect on the HPG axis which results in a fall in the testosterone levels, which causes changes in Sertoli cells and the blood-testis barrier leading to the arrest of spermatogenesis (Makanjuola *et al.* 2010).

Anxiety and depression could activate an inhibitory effect on the female reproductive system. Corticotrophin releasing hormone (CRH) inhibits hypothalamic gonadotropin-releasing hormone (GnRH) secretion, and glucocorticoids inhibit pituitary luteinizing hormone and ovarian estrogen and progesterone secretion. These are responsible for the 'hypothalamic' amenorrhea (Abasiubong *et al.* 2008).

It is recommended that infertile couples desiring conception are encouraged to avoid anxiety and depression and management programs such as periodic relaxation

activities are encouraged to improve conception rates (Silvestris *et al.* 2019).

Perception and belief

Another major challenge is the wrong perceptions and beliefs among the non-enlightened majority in developing countries particularly in West Africa about infertility and some of the available treatments (Adesiyun *et al.* 2011, Okwelogu *et al.* 2012, Okafor *et al.* 2017, Omokanye *et al.* 2017, Akande *et al.* 2019). Some believed that infertility is caused by evil spirits, predestined by God, punishment from God and supernatural challenge. Other perceived it as a curse that requires prayers and patience to be resolved (Okafor *et al.* 2017). This perception may not be limited to West Africa or Nigeria as a study from Karachi, Pakistan also revealed that evil forces and supernatural forces were considered as causes of infertility especially among people with low educational status (Akande *et al.* 2019). On the contrary, findings from several studies have shown infertility to be a disease condition or medical challenge rather than a social problem (Umeora *et al.* 2008, Okwelogu *et al.* 2012, Osian *et al.* 2019).

Advances in medical sciences have proven that infertile conditions are treatable. Various types of assisted reproductive technologies are available in the management of infertility. However, negative attitude, wrong perception and beliefs have been associated with IVF, which has been successfully used in the treatment of infertility especially among the un-enlightened individuals. Majority of respondents surveyed by some authors perceived IVF as un-natural and not cultural. The held perception of children conceived through this procedure is abnormal or inferior to those conceived naturally (Okafor *et al.* 2017, Akande *et al.* 2019). Despite the suggestion by earlier study that the wrong perception of IVF was due to the nascent nature of the technology (Giwa-Osagie 2002), the negative attitude and wrong perception still exists. As a result of misconception, lack of awareness and beliefs, ART treatment is conducted secretly to avoid stigmatization in Nigeria (Okafor *et al.* 2017). This may adversely impacts the treatment since seeking care for infertility is associated with supernatural forces, which requires supernatural methods to resolve. Lack of awareness of IVF in most countries of sub-Saharan Africa has posed a very strong challenge to its acceptability and utilization (Okafor *et al.* 2017).

The misconception and belief is very common among the uneducated and so strong that even the educated ones have some reservations due to the strong family support

system being practiced. As a result, there is usually a delay in the willingness to access treatment because they want to 'wait on God' for the natural process of conception (Adesiyun *et al.* 2011, Omokanye *et al.* 2017). This practice further reduces the chances of hitherto healthy individuals that would have benefited from the treatment particularly those with unexplained infertility who could afford the cost of the technique. Therefore, individuals have a responsibility to preserve or increase their fertility potential to some degree by modifying their lifestyle behaviors which may improve or hamper their reproductive health. The authors advocate reproductive health education to create the necessary awareness of the etiologies of infertility and the importance of IVF treatment as a means of conceiving 'natural' babies.

Some factors impairing effective treatment of infertility

Some of the identified factors militating against the effective treatment of infertility include; high cost and inaccessibility of most couples in need, absence of specific objectives, priorities, and strategies for infertility care in most countries in sub-Saharan Africa, absence of reliable data and good follow-up mechanisms, lack of integration of infertility services into the reproductive health services, absence of proper coordination of healthcare system, inability to accurately target those at risk for infertility and inadequate training and research in infertility (Leke 2019). Some authors in Nigeria have observed that despite the great burden of the condition, only very few infertility management programs are available (Okafor *et al.* 2017). Fertility care, development, and access are limited. Therefore, the burden of infertility lies sorely on the couple (Akande *et al.* 2019). It was observed that most infertile couples belong to the very poor in the society, hence would not be able to afford the high cost of treatment (Agholor 2017), as a result, most couples discontinue or abandon their treatment. The most common cause of female infertility in Nigeria is a pelvic factor especially tubal blockage (probably due to post-infectious causes such as sexually transmitted infections, post abortal, and puerperal sepsis) and the best treatment is by Assisted Reproductive Technology methods. The cost of a cycle of *in vitro* fertilization is above one million Naira. To make matter worse, the success rate is low (20–30%), and as such a couple may require more than one cycle to achieve success. This does not only lead to emotional and psychological trauma but increase poverty (Agholor 2017).

Stress is a modifiable factor that adversely impact treatment success of infertility. Stress is regarded as any uncomfortable 'emotional experience' accompanied by predictable biochemical, physiological, and behavioral changes or responses. Many forms of stress including physical, social, or psychological is a modern lifestyle, which can lead to reproductive treatment failure. Stress does not only lead to treatment failure but can cause infertility or it may arise from infertility (Aydin *et al.* 2014). The psychosocial-induced stress can affect fertility treatment if not avoided. It can lead to impaired gonadotrophin-release, low serotonin secretion, and elevated prolactin level. Also, it may cause abnormal function of the immune system which may adversely impact fertility-related antibodies (Aydin *et al.* 2014).

Practical recommendations to modify lifestyle behaviors

Age plays a major role in determining the fertility of both partners. Couples need to consider the age of the partners before marriage so that the chances of conception are increased. The peak of fecundability is before age 35 for men and 30 for women. Infertile couples should access care early after a maximum of one year without conception and 6 months among older couples.

Couples trying to achieve pregnancy should limit or quit smoking since there appears to be a significant impact of smoking on reproductive outcomes. The risk of miscarriage will be reduced and menopause will be delayed by 4 years. Also, passive smoking should be avoided.

Research shows that weight plays a significant role in fertility, therefore; maintaining a healthier weight will help to prevent hormonal imbalance which adversely affects fertility thereby improving ovulation and the risk of miscarriage and other complications. Overweight infertile women on treatment are encouraged to reduce weight for effective treatment outcomes.

It is better to reduce or abstain from alcohol consumption when trying to achieve pregnancy. Caffeine also appears to have a negative effect and should also be consumed with caution.

Infertile couples should avoid anxiety and emotional stress, but embark on relaxation programs to reduce other sources of stress to increase fertility. Moderate regular exercises could help to release endorphins which would help relaxation.

Nutrition and exercise may impact fertility both in men and women, good nourishment and a balanced

diet should be encouraged. Infertile women should consume foods low in saturated fat, red meat, and high in vegetables, legumes, and antioxidants.

Recreational and prescription drugs have a significant impact on fertility as most of these drugs alter reproductive processes. It is therefore best to avoid all unnecessary medications and recreational drugs.

Avoiding excessive irradiation by reducing contact with electronic gadgets like mobile phones that emit electromagnetic waves may prevent infertility. It is not possible to eliminate all hazards in the environment, but efforts can be made to reduce them.

Conclusion

Most lifestyle factors are theoretically modifiable habits that can be reversed with strong determination by affected subjects. Public enlightenment by health care providers will go a long to increasing the knowledge and improve the awareness of the population since most are not aware of the potential consequences of lifestyle habits on infertility. Counseling of infertile couples may enhance awareness of the risk of lifestyle behaviors and facilitate appropriate lifestyle changes that might improve reproductive health. Educational and career pursuits could be combined with childbearing and the government should provide facilities such as day-care and nursery within the working environment to encourage prospecting mothers. Public health enlightenment campaigns that will educate on the harmful effects of drug and substance abuse should be intensified. Appropriate legislation and enforcement of laws that regulate these drugs coupled with the punishment of offenders may help to check the negative impact of substance abuse by individuals and society at large.

Declaration of interest

The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of this review.

Funding

This research did not receive any specific grant from any funding agency in the public, commercial or not-for-profit sector.

Author contribution statement

This work was conducted and approved in collaboration between the authors. M A designed the study; M A E, S I B contributed to literature search; S I B drafted the manuscript; M A E wrote the final manuscript; M A E proofread the manuscript.
